ABSTRACT Disintegration of the colonic epithelial barrier is considered a key event in the initiation and progression of inflammatory bowel and celiac disease. As the primary etiology of these diseases remains unknown, we hypothesized that the trichothecene deoxynivalenol (DON), a fungal metabolite found in grain-based human diets, might be one of the triggers resulting in an impairment of the intestinal tight junction network preceding an inflammatory response. Using horizontal impedance measurements, we demonstrate that DON disintegrates a human Caco-2 cell monolayer within <1 h after exposure to concentrations as low as 1.39 μM. This initial trigger is followed by a decrease in transepithelial resistance and an increased permeability of marker molecules, such as lucifer yellow and FITC-labeled dextran. In parallel, the increase in paracellular transport of FITC-dextran is demonstrated in vivo in B6C3F1 mice, challenged orally with DON. In vitro claudin protein levels are decreased and correlated with a displacement within the cells in vitro and in vivo, accompanied by a compensatory up-regulation of mRNA levels of Claudins and their binding partner ZO-1. In treated mice, alterations in villus architecture in the entire intestinal tract resemble the disintegration of the epithelial barrier, a characteristic of chronic inflammatory bowel disease.—Akbari, P., Braber, S., Gremmels, H., Koelink, P. J., Verheijden, K. A. T., Garssen, J., Fink-Gremmels, J. Deoxynivalenol: a trigger for intestinal integrity breakdown. FASEB J. 28, 000–000 (2014). www.fasebj.org

Key Words: Caco-2 cells • TEER • tight junction proteins

The intestinal epithelial barrier is essential for the maintenance of physiological gut functions and serves as the first line of host defense against potentially harmful stressors from the environment, such as bacteria and viruses, as well as natural antigens and toxins occurring in food (1–3). The physical intestinal barrier is primarily formed by epithelial cells, connected by tight junctions (TJs), which form an anastomosing network sealing adjacent epithelial cells near the luminal surface, thus preventing a paracellular transport of luminal antigens (4, 5). TJs are composed of transmembrane proteins, including occludin (OCLN) and Claudins (CLDNs), which form a linear barrier at the apical-lateral membrane of the cell; peripheral membrane proteins, like zona occludens (ZO) proteins, that serve as a link between the transmembrane TJ proteins; and cytosolic and nuclear proteins (6, 7). It is well accepted that a breakdown of the normally impeccable epithelial barrier of the intestine results in the development of a “leaky” gut. Disintegrated intestinal TJs allow the paracellular infiltration of luminal antigens and are considered as a pivotal pathogenic factor in the onset and promotion of chronic intestinal inflammations, such as inflammatory bowel disease (IBD) and celiac disease (8–10). Recent experimental evidence suggests that certain food contaminants, in particularly the mycotoxin deoxynivalenol (DON) can impair intestinal barrier functions (11–14) and may be directly involved in intestinal inflammation (15–17). DON, a Fusarium metabolite, is among the most frequently detected contaminants of cereal-based foods, including breakfast cereals (18–21). Considering this regular human exposure, the aim of the current study was to characterize the sequence of events induced by DON that leads to a compromised intestinal barrier function. Using human Caco-2 cell monolayers as an in vitro model, we investigated the effect of DON on barrier integrity following apical and basolateral exposure, the paracellular transport of marker molecules, and alter-
ations in the expression and cellular distribution of TJ proteins. In vitro experiments in male B6C3F1 mice, challenged orally with DON, were conducted to substantiate the in vitro findings and to demonstrate the effect of DON exposure on villus architecture. The presented results challenge the hypothesis that nutritional DON exposure and the postulated high concentrations of the toxin in the intestinal lumen are the possible explanation for the observed translocation of luminal pathogens, while at the same time providing convincing evidence that DON acts as a trigger for intestinal integrity breakdown.

MATERIALS AND METHODS

DON solution

Purified DON (D0156; Sigma-Aldrich, St Louis, MO, USA) was dissolved in absolute ethanol (99.9%; J.T. Baker, Deventer, The Netherlands) to prepare a 25 mM stock solution, stored at −20°C. Serial dilutions of this stock were prepared in cell culture medium. All other chemicals were of the highest purity available.

In vitro experiments

Caco-2 cell cultures

Human epithelial colorectal adenocarcinoma cells (Caco-2 line, passages 5–19; HTB-37; American Type Culture Collection, Manassas, VA, USA) were cultured in 75-cm² culture flasks (Greiner Bio-One, Frickenhausen, Germany) in Dulbecco’s modified Eagle’s medium (DMEM), containing 25 mM HEPES and 4.5 mM/L glucose (Life Technologies, Inc., Invitrogen, CA, USA), and supplemented with 10% heat-inactivated fetal calf serum (Life Technologies), 100 U/ml penicillin, 100 g/ml streptomycin, and 2 mM glutamine (Biocambrex, Verviers, Belgium), and 1% nonessential amino acids (Life Technologies). The cells were maintained in a humidified atmosphere of 95% air and 5% CO₂ at 37°C. Medium was refreshed every 2–3 d, and cells were passaged in a humidified atmosphere of 95% air and 5% CO₂ at 37°C. Medium was refreshed every 2–3 d, and cells were passaged 1×/wk. For subculture, the confluent cells were trypsinized using 0.05% trypsin and 0.54 mM EDTA and were diluted in culture medium.

Caco-2 cell monolayers on transwell inserts

All in vitro experiments were conducted with Caco-2 cells grown on 0.3-cm² high-pore-density polyethylene terephthalate membrane transwell inserts with 0.4-μm pores (Falcon; BD Biosciences, Franklin Lakes, NJ, USA) placed in a 24-well plate, if not otherwise stated. The cells were seeded at a density of 0.3 × 10⁵ cells/insert. The cells were incubated at 37°C in a humidified atmosphere of 95% air and 5% CO₂. After 17–19 d of culture, a confluent monolayer was achieved, with a mean transepithelial electrical resistance (TEER) exceeding 400 Ω·cm² measured by a Millicell-ERS volt-ohm meter (Millipore, Temecula, CA, USA). Each transwell experiment started when the TEER values reached this plateau.

Lactate dehydrogenase (LDH) assay

Caco-2 cells grown on inserts as described above were exposed to DON (0–37.5 μM) for 24 h, and the cytotoxic effect of DON on the Caco-2 cells was evaluated by measuring LDH leakage. LDH leakage was measured in the culture medium of the apical and basolateral compartments using the CytoTox 96 nonradioactive cytotoxicity assay kit (Promega Corp., Madison, WI, USA), according to manufacturer’s instructions.

TEER measurement

Caco-2 cells were grown on inserts as described above. The integrity of the cellular monolayer was evaluated by measuring TEER using a Millicell-ERS volt-ohm meter (Millipore). Mean TEER values for untreated cell monolayers were 435 ± 15 Ω·cm². The cells were challenged by adding increasing concentrations of DON (0, 0.05, 0.15, 0.46, 1.39, 4.17, and 12.5 μM) to the apical side, the basolateral side, or both sides. TEER was measured at 0, 2, 4, 8, 12, and 24 h after DON exposure.

Paracellular tracer flux assay

Caco-2 cell monolayers grown on inserts as described above were treated with increasing concentrations of DON in the apical and basolateral compartments for 24 h. Thereafter, membrane-impermeable molecules such as lucifer yellow (LY, molecular mass of 0.457 kDa, 6 μg/ml; Sigma-Aldrich) and two different molecular sizes of fluorescein isothiocyanate (FITC)-dextran (molecular mass of 4 and 40 kDa, respectively, 6 μg/ml; Sigma-Aldrich) were added to the apical compartment for 4 h, and paracellular flux was determined by measuring the fluorescence intensity in the basolateral compartment with a fluorometer (FLUOstar Optima; BMG Labtech, Offenburg, Germany) set at excitation and emission wavelengths of 410 and 520 nm, respectively, for LY, and 485 and 520 nm for FITC-dextran.

Real-time horizontal impedance measurements

The xCelligence system (Roche Applied Science, Mannheim, Germany) was used for dynamic monitoring of epithelial barrier integrity, as described before (22, 23). Briefly, 50 μl of the culture medium was added to 16-well E-plates (Roche Diagnostics, Mannheim, Germany) to obtain background readings of the individual wells. Caco-2 cells were seeded into these plates at a density of 5000 cells/well in 100 μl medium and grown for ~2 d to reach confluence, as indicated by a plateau in impedance signal. Since dome formation (24) may lead to detachment of the Caco-2 cells in this E-plate (not observed in transwell inserts) and decreased impedance measurements (from 60–72 h), the real-time horizontal impedance measurements started 2 d postseeding to prevent effects of dome formation on these measurements. DON was added at increasing concentrations (0, 1.39, 4.17, and 12.5 μM) applied in temperature-equilibrated medium, followed immediately by real-time impedance measurements every 5 min over a period of 24 h. Impedance measurements were recorded at frequencies of 10, 25, and 50 kHz, from which a compound signal, referred to as the cell index, was created (25). The relative change in impedance at a certain time point was calculated by dividing the cell index value by the reference time point (time 0) and corrected in relation to the control condition. Area under the curve (AUC) of each replicate was calculated for statistical analysis.

In vitro expression of TJ proteins: isolation of RNA and qRT-PCR analysis of Caco-2 cells

Caco-2 cell monolayers were grown on inserts and exposed to increasing concentrations of DON in the apical and basolat-
eral compartments for 3, 6, and 24 h. Thereafter, cells were washed twice with ice-cold PBS and were harvested into 100 μl RNA lysis buffer with β-mercaptoethanol. Total RNA was isolated using spin columns (Promega) according to the manufacturer’s instructions. RNA amounts were determined spectrophotometrically, and RNA purity was measured by NanoDrop 2000 (Thermo Scientific, Waltham, MA, USA) as A260/A280 ratio with expected values between 1.8 and 2. Subsequently, 1 μg of extracted total RNA was reverse transcribed with the iScript™ cDNA Synthesis kit (Bio-Rad Laboratories, Hercules, CA, USA). The cycling protocol for 20 μl reaction mixes was 5 min at 25°C, followed by 30 min at 42°C, and 5 min at 85°C to terminate the reaction. After reverse transcription, cDNA was stored at −20°C. cDNA was diluted with nuclease-free water (1:9) directly before qRT-PCR analysis. The reaction mixture for the qRT-PCR, containing 10 μl of the diluted cDNA mixed with 12.5 μl iQSYBR Green Supermix (Bio-Rad Laboratories), forward and reverse primers (final concentration of 300 nM for each primer), and sterile deionized water, was prepared according to manufacturer’s instructions. qRT-PCR was performed using the MyIQ single-color real-time PCR detection system (Bio-Rad Laboratories) and MyIQ System 1.0.410 software (Bio-Rad Laboratories). PCR cycle parameters were as follows: general denaturation at 95°C for 3 min, 1 cycle, followed by 40 cycles of 95°C for 20 s, annealing temperature (AT) for 30 s, and elongation at 72°C for 30 s. Gene-specific primers for CLDN1, CLDN 3, CLDN4, OCLN, and ZO protein 1 (ZO-1) (Table 1) were derived from the U.S. National Center for Biotechnology Information (NCBI; Bethesda, MD, USA) GenBank and were manufactured commercially (Eurogentec, Seraing, Belgium).

Specificity and efficiency of selected primers (Table 1) were confirmed by qRT-PCR analysis of dilution series of pooled cDNA at a temperature gradient (55–65°C) for primer annealing and subsequent melting curve analysis. The geNorm 3.5 software (Ghent University, Ghent, Belgium) was used to identify the most stable reference genes for this experiment. The mRNA quantity was calculated relative to the expression of two reference genes, glyceraldehyde 3-phosphate dehydrogenase (GAPDH) and β-actin (ACTB). No significant effect of DON exposure on the Ct values of GAPDH and ACTB of two reference genes, glyceraldehyde 3-phosphate dehydrogenase (GAPDH) and β-actin (ACTB). No significant effect of DON exposure on the Ct values of GAPDH and ACTB was observed (data not shown).

**Western blot analysis**

Caco-2 cell monolayers were grown on inserts and incubated with increasing concentrations of DON in the apical and basolateral compartments for 24 h. Caco-2 monolayers were washed twice with cold PBS, and cells were lysed with 50 μl RIPA lysis buffer (50 mM Tris, 150 mM NaCl, 0.5% DOC, 1% Nonidet P-40, and 0.1% SDS, pH 8.0; Thermo Scientific) containing protease inhibitors (Roche Applied Science). After 5 min incubation with RIPA buffer, monolayers were harvested and centrifuged at 14,000 g for 15 min to yield a clear lysate. Total protein content was determined using the BCA protein assay (Thermo Scientific) following the manufacturer’s instructions. Equal protein amounts of heat-denatured nonreduced samples were separated electrophoretically (Criterion gel, 4–20% Tris-HCl; Bio-Rad Laboratories) and electrotransferred onto polyvinylidene difluoride membranes (Bio-Rad, Veenendaal, The Netherlands). The membranes were blocked with PBS containing 0.05% Tween-20 (PBST) and 5% milk proteins for 1 h at room temperature. Subsequently, the primary antibodies CLDN1, CLDN3, CLDN4, OCLN, and ZO-1 (Invitrogen; see Supplemental Table S1), diluted according to manufacturer’s instructions, were incubated overnight at 4°C, followed by washing the blots in PBST. Secondary antibodies (Dako, Glostrup, Denmark) were applied for 2 h at room temperature. Blots were washed in PBST and incubated in commercial ECL reagents (Amersham Biosciences, Roosendaal, The Netherlands), and exposed to photographic film. Membranes were subsequently reprobed with rabbit monoclonal anti-human ACTB antibody (Cell Signaling, Danvers, MA, USA; see detailed information in Supplemental Table S1) to assess homogeneity of loading. Films were scanned on a GS710 calibrated imagine densitometer (Bio-Rad Laboratories) and the optical density (OD) for the immunoreactive bands was quantified.

**Immunofluorescence staining Caco-2 cells**

Cellular localization of TJ proteins was assessed by immunofluorescence. Caco-2 cells were grown on inserts and exposed to 4.17 μM DON in the apical and basolateral compartments for 24 h. Subsequently, the inserts with cells were fixed with 10% formalin for 10 min. After washing with PBS, the cells were permeabilized with PBS containing 0.1% Triton-X-100 for 5 min, and blocked with 5% serum for 30 min at room temperature. Thereafter, the samples were incubated (2 h, room temperature) with different primary antibodies CLDN1, CLDN3, CLDN4, OCLN, and ZO-1 (Invitrogen; see Supplemental Table S1) diluted in PBS containing 1% BSA according to manufacturer’s instructions. The negative control lacking the primary antibodies was included (Supplemental Fig. S3). Samples were rinsed with PBS followed by incubation with Alexa-Fluor conjugated secondary antibody (Life Technologies) for 1 h at room temperature. A nuclear counterstaining was performed by incubating the samples for 1–3 min with Hoechst 33342 (1:2000; Invitrogen). After washing, the inserts were mounted with ProLong Gold antifade reagent. Immunolocalization of TJ proteins was visualized and images were taken using the Nikon Eclipse TE2000-U microscope equipped with a Nikon Digital Sight DS-U1 camera.

AT, annealing temperature (°C).
**In vivo experiments**

**Animals**

Male B6C3F\(_1\) mice (\(n=5–6/\text{group}\)), 6–7 wk old (Charles River Laboratories, Maastricht, The Netherlands) were housed under controlled conditions in standard laboratory cages and were acclimated to the in-house environment for 2 wk. The room was maintained on a 12-h light-dark cycle at ~20.5°C with a relative humidity of ~61.5%. The AIN-93G-based diet (26), composed by Research Diet Services (Wijk-bij-Duurstede, the Netherlands), and water were provided ad libitum. The AIN-93G-based diet was checked for DON contamination by standard HPLC analyses with affinity column cleanup based on the method described in Dombrink-Kurtzman et al. (27), and no DON contamination exceeding the limit of 10 \(\mu\)g/kg feed was detected. All *in vivo* experimental protocols were approved by the Ethics Committee for Animal Experiments (DEC 2012.III.02.012) and were performed in compliance with governmental and international guidelines on animal experimentation.

**DON gavage and FITC-dextran permeability assay**

Feed was withdrawn from cages 2 h before toxin administration. DON, dissolved in 200 \(\mu\)l PBS, was administered at a dose of 25 mg/kg BW by oral gavage. Control animals received 200 \(\mu\)l of vehicle. The 25 mg/kg dose represents approximately one-third to one-half of the LD\(_{50}\) for DON in mice (28). At 2 h after DON administration, all animals received FITC-dextran (500 mg/kg BW; molecular mass 4 kDa; Sigma-Aldrich) by an oral gavage. The appearance of FITC-dextran in blood serum was measured 4 h after the FITC-dextran gavage (6 h after DON administration). Directly after cervical dislocation, blood was obtained by heart puncture and collected in MiniCollect Z Serum Sep tubes (Greiner Bio-One). After 1 h, the clotted blood samples were centrifuged for 10 min at 14,000 rpm and the sera were collected. Standard curves were obtained by a serial dilution of FITC-dextran in serum of mice that did not receive FITC-dextran and were not included in this experiment.

Serum samples from treated animals were diluted in an equal volume of PBS and the amount of FITC-dextran determined by measuring the fluorescence intensity using a spectrofluorometer (FLUOstar Optima; BMG Labtech) set at excitation and emission wavelengths of 485 and 520 nm, respectively. The appearance of FITC-dextran in blood serum was measured 4 h after the FITC-dextran gavage (6 h after DON administration). Directly after cervical dislocation, blood was obtained by heart puncture and collected in MiniCollect Z Serum Sep tubes (Greiner Bio-One). After 1 h, the clotted blood samples were centrifuged for 10 min at 14,000 rpm and the sera were collected. Standard curves were obtained by a serial dilution of FITC-dextran in serum of mice that did not receive FITC-dextran and were not included in this experiment.

**Histomorphometric analysis of mouse intestines**

The proximal small intestine and distal small intestine were fixed in 10% neutral buffered formalin and embedded in paraffin as a “Swiss roll” (29) to permit a complete microscopic examination. After paraffin embedding, 5-\(\mu\)m sections were cut (2–3 sections/antibody/animal). These Swiss-rolled paraffin sections were deparaffinized, endogenous peroxidase activity was blocked with 0.3% H\(_2\)O\(_2\) (Merck, Darmstadt, Germany) in methanol for 30 min at room temperature and rehydrated in a graded ethanol series to PBS. For antigen retrieval, the slides were boiled in 10 mM citrate buffer (pH 6.0) for 10 min in a microwave. The slides were cooled down to room temperature, rinsed with PBS (3\(\times\)) and blocked with 5% serum for 30 min at room temperature. Thereafter, the immunofluorescence staining protocol with the primary antibodies CLDN1, CLDN2, CLDN3, CLDN4, OCLN (Invitrogen), and ZO-1 (Millipore) (see Supplemental Table S1) was performed as described above. The negative controls lacking the primary antibodies were included (Supplemental Fig. S3B–D).

**Immunofluorescence staining of mouse intestinal specimens**

The proximal small intestine and distal small intestine were fixed in 10% neutral buffered formalin and embedded as a “Swiss roll” (29). After paraffin embedding, 5-\(\mu\)m sections were cut and stained with hematoxylin and eosin (H&E) according to standard methods. Photomicrographs were taken with an

AT, annealing temperature (°C).
Olympus BX50 microscope (Olympus Europa GmbH, Hamburg, Germany) equipped with a Leica DFC 320 digital camera (Leica Microsystems, Wetzlar, Germany). The morphometric analysis of the sections was performed on 10 randomly selected, well-oriented villi and crypts per animal. A computerized microscope-based image analyzer (Cell' D; Olympus) was used to determine histomorphometric parameters: villus height (measured from the tip of the villus to the villus-crypt junction), crypt depth (measured from the crypt-villus junction to the base of the crypt), villus width, villus surface area (total surface of the villus) and epithelial cell area (villus area minus villus area without epithelial cells). These regions of interest were manually defined for each villus separately; an example of the histomorphometric analysis of a villus is depicted in Supplemental Fig. S1.

Statistical analyses

Experimental results are expressed as means ± SEM. Analyses were performed by using GraphPad Prism 5.0 (GraphPad, La Jolla, CA, USA). Differences between groups were statistically determined by using 1-way ANOVA, with Bonferroni post hoc test for in vitro experiments and an unpaired 2-tailed Student’s t test for in vivo experiments. Results were considered statistically significant when \( P < 0.05 \).

RESULTS

Cytotoxic effects of DON in Caco-2 cells

The direct cytotoxicity of DON was measured over a concentration range between 0 and 37.5 \( \mu M \) by the LDH leakage assay. DON did not impair cell viability, as indicated by LDH release in apical and basolateral compartments up to a concentration of 12.5 \( \mu M \). LDH release increased slightly, but not significantly, at this concentration (Fig. 1). In all forthcoming experiments, DON concentrations \( \leq 12.5 \mu M \) were used.

![Figure 1. DON did not exert cytotoxic effects on Caco-2 cells. Caco-2 cells grown on inserts were incubated with increasing concentrations of DON (0, 1.39, 4.17, 12.5, and 37.5 \( \mu M \)) for 24 h, followed by measurement of LDH release in the apical as well as the basolateral compartment of the transwell insert system. Results are expressed as mean ± SEM percentage of LDH released by the nontreated cells of 3 independent experiments, each performed in triplicate.](image)

Effects of DON on TEER of a Caco-2 monolayer

On exposure to increasing concentrations of DON (0, 0.05, 0.15, 0.46, 1.39, 4.17, and 12.5 \( \mu M \)) added to the apical and basolateral compartments, a clear dose-response curve was obtained. Concentrations up to 0.46 \( \mu M \) DON remained without any effect, whereas the following test concentration of 1.39 \( \mu M \) resulted in a highly significant decrease of the TEER value (Fig. 2A). To assess the differences in the routes of exposure, DON was added to either the apical or the basolateral side, or to both sides of the transwell chamber (Fig. 2B). Results show that after basolateral exposure to DON, the decrease of TEER values was more pronounced compared to the alterations observed after apical exposure to DON (Fig. 2B), where only small effects were observed. The TEER decrease after dual exposure to DON from the apical and basolateral side was comparable with the decrease in TEER values after basolateral exposure (Fig. 2B). Since, DON is quickly and expeditiously absorbed in the upper parts of the small intestine (30), and following absorption it is likely to be secreted into the gut lumen as DON is a substrate for ABC efflux transporters (31), exposure to both apical and basolateral side mimics the in vivo situation and will be used in the following experiments. The time dependency was established in experiments using increasing concentrations of DON (1.39, 4.17, and 12.5 \( \mu M \)), which were added to the apical as well as to the basolateral side. Different incubation time points (2, 4, 8, 12, and 24 h) were tested, and a time-dependent decrease in TEER was observed (Fig. 2C). The first significant TEER decrease by DON was observed after 8 h.

DON increases permeability of Caco-2 monolayer

Monitoring the permeability of the paracellular transport markers LY (0.457 kDa) and two different molecular sizes of FITC-dextran (4 and 40 kDa, respectively) across the cell monolayer (Fig. 3) indicated that DON (added to both apical and basolateral compartments) induced a significant increase in the translocation of LY (0.457 kDa) and 4 kDa FITC-dextran from the apical to the basolateral chamber (Figs. 3A and 4B). However, DON exposure (both apical and basolateral) did not affect the Caco-2 monolayer permeability of 40-kDa FITC-dextran, which remained unchanged (Fig. 3B).

DON induces a decline in impedance values after real-time monitoring

Real-time recording of the horizontal impedance every 5 min over a period of 24 h following exposure of a Caco-2 monolayer to 3 different concentrations of DON (1.39, 4.17, and 12.5 \( \mu M \)) showed an immediate and concentration-dependent decline in impedance values commencing within the first 15 min of DON exposure and lasting for almost the entire observation period (Fig. 4A). Lines of individual experiments were summarized as AUC, and this summary measure was used for statistics (in a separate
DON up-regulates mRNA expression of TJ proteins in Caco-2 cells

To correlate the DON-induced impaired integrity with barrier dysfunctions, the mRNA expression levels of the different TJ proteins (CLDN1, CLDN3, CLDN4, OCLN, and ZO-1) were measured. Caco-2 cell monolayers, grown on inserts, were exposed to increasing concentrations of DON (1.39, 4.17, and 12.5 μM) in the apical and basolateral compartments for 3, 6, or 24 h. RT-PCR analysis demonstrated that already after 3 h of DON exposure, the mRNA expression levels of CLDN3, CLDN4, and ZO-1 were up-regulated in a concentration-dependent manner (Fig. 5A). After 6 h of DON exposure, the mRNA expression levels of all TJ proteins were dose-dependently increased (Fig. 5B). The mRNA expression of the TJ proteins in Caco-2 cells after 24 h of DON exposure was statistically determined using 1-way ANOVA tests to examine differences between groups.
exposure was comparable with the results after 6 h of DON exposure (Fig. 5C).

**DON selectively affects TJ protein levels in Caco-2 cells**

Next to the assessment of mRNA expression of the TJ proteins, the effect of DON on the protein levels of several TJs (CLDN1, CLDN3, CLDN4, OCLN, and ZO-1) were quantified by Western blot analysis in Caco-2 cell lysates of cells that had been exposed to DON in the apical and basolateral compartments for 24 h. A representative blot of each TJ protein and the corresponding ACTB used as loading control are shown in Fig. 6A, B (additional blots are available in Supplemental Fig. S2). The optical density of the molecular weight bands of the different TJ proteins was measured and after normalization with ACTB also depicted in Fig. 6A, B. A dose-dependent reduction of the CLDN1, CLDN3, and CLDN4 protein levels was observed in DON-exposed Caco-2 cells compared to untreated cells (Fig. 6A). The OCLN and ZO-1 levels remained unchanged after DON challenge (Fig. 6B).

**DON affects distribution pattern of TJ proteins in Caco-2 cells**

To investigate the cellular localization of TJ proteins, Caco-2 cell monolayers grown on inserts were incubated with or without DON (4.17 µM) at apical and basolateral compartments for 24 h, followed by an immunofluorescent staining. In the intact Caco-2 cells, CLDN1, CLDN3, CLDN4, OCLN, and ZO-1 are localized at the cell membrane and appeared as continuous belt-like structures encircling the cells at the contact points with adjacent cells (Fig. 6A, B). DON exposure disturbed the continuity of all tested TJ proteins, which appeared to be irregular distributed in the cells (Fig. 6A, B).

**In vivo exposure of B6C3F1 mice to DON results in increased intestinal permeability**

To confirm the DON-induced hyperpermeability observed in the Caco-2 monolayer, an in vivo intestinal permeability assay was performed in a mouse model using the paracellular tracer FITC-dextran (4 kDa). This tracer was significantly increased in serum of DON-treated mice when measured 4 h after a FITC-dextran oral gavage (Fig. 7). This finding indicates that DON induced an increase in the in vivo intestinal permeability observed by the translocation of FITC-dextran across the intestinal interfaces in B6C3F1 mice.

**DON selectively up-regulates mRNA expression of TJ proteins in different parts of mouse intestines**

To extrapolate the DON-induced induction in mRNA expression of different TJ proteins observed in Caco-2 cells, the mRNA expression levels of the same TJ proteins (CLDN1, CLDN2, CLDN3, CLDN4, OCLN, and ZO-1) were measured in different segments of the mouse intestines (proximal, middle, and distal small intestine, caecum, and colon). CLDN4 mRNA expres-
sion levels were increased in all parts of the intestines of the DON-treated animals compared to the control animals (Fig. 8A–E), whereas CLDN3 expression levels were increased after DON gavage in all parts of the intestines, except the proximal and middle small intestine (Fig. 8C–E). The mRNA expression levels of CLDN2 were increased in the mouse middle and distal small intestine on DON exposure as compared to the nontreated animals (Fig. 8B, C).

The ZO-1 mRNA expression levels were only increased in the proximal small intestine of the DON-treated animals (Fig. 8A). The mRNA expression of OCLN and CLDN1 remained unaffected in all parts of the intestines of DON-exposed mice compared to control mice.

**DON affects distribution pattern of TJ proteins in intestines of mice**

Considering that DON selectively up-regulated the mRNA levels of the TJ proteins in the mouse intestines, especially in the distal part of the small intestine, immunofluorescence stainings of all TJ proteins

---

**Figure 5.** DON up-regulated mRNA expression of TJ proteins in Caco-2 cells. Caco-2 cells were grown on inserts and stimulated with increasing concentrations of DON (1.39, 4.17, and 12.5 μM) in apical and basolateral compartments for 3 (A), 6 (B), and 24 h (C). mRNA levels of TJ proteins (CLDN1, CLDN3, CLDN4, OCLN, and ZO-1) were measured by qRT-PCR, as described in Materials and Methods. Results are expressed as mean ± SEM relative mRNA expression of 3 independent experiments, each performed in triplicate. *P < 0.05, **P < 0.01, ***P < 0.001 vs. 0 μM DON.
(CLDN1, CLDN2, CLDN3, CLDN4, OCLN, and ZO-1) were performed to show the cellular distribution and localization of TJ proteins. Results show that in the distal small intestine of control mice, CLDN1 and CLDN3 were expressed laterally between adjacent cells with neither a specific signal at the apical cell surface nor on the basal membrane. After DON gavage, the CLDN1 and CLDN3 expression was more pronounced laterally and at the basal cytoplasm (Fig. 8). CLDN2 distribution was restricted to the villus crypts in the distal small intestine of control animals and was expressed laterally between adjacent cells. This CLDN2 expression pattern was disrupted after DON gavage. In contrast to the controls, CLDN2 expression was not restricted to the villus crypts anymore (Fig. 8). CLDN4 was expressed in both the tips and crypts of the villi in the distal small intestine. These findings clearly indicate that the expression of CLDN4 is restricted to selective sites and cannot be found on every tip or crypt of the villus epithelium. No pronounced effect on the CLDN4 distribution pattern in the distal small intestine was observed after the DON gavage (Fig. 8). Unlike the distribution pattern of the CLDNs, expressed laterally between adjacent cells in the distal small intestine, OCLN and ZO-1 were localized in distinct dot-like structures at the apical region of the lateral plasma membrane of the epithelial cells of a villus, and no clear alterations were observed after DON exposure (Fig. 8). In addition, immunofluorescence stainings of different TJ proteins (CLDN1, CLDN2, CLDN3, CLDN4, OCLN, and ZO-1) were performed in the colon of control and DON-treated animals, to investigate whether the distribution pattern of TJ proteins in the colon is affected by DON. No clear differences in the distribution patterns of CLDN1, CLDN2, CLDN3, CLDN4, OCLN, and ZO-1 were observed in the colon of DON-treated animals compared to control animals (Supplemental Fig. S4).

DON induces histomorphological changes in intestines of mice

A quantitative histomorphometric analysis of the proximal and distal small intestine showed a significant decrease in villus height and villus area in the proximal (Fig. 9A) as well as in the distal small intestine (Fig. 9B) of DON-exposed mice in comparison to the nontreated animals. Furthermore, the epithelial cell area of the DON-treated mice was also significantly diminished in both proximal (Fig. 9A) and distal small intestine (Fig. 9B). The crypt depth was only increased in the proximal small intestine of the DON-treated mice compared to nontreated mice (crypt depth: control, 131.71±5.20 μm; DON, 168.50±7.65 μm; P≤0.01), while no changes in villus width were observed in both parts of the small intestine followed by DON treatment.

DISCUSSION

A compromised intestinal barrier function has been associated with various diseases, including inflammatory bowel disease, celiac disease, and irritable bowel syndrome. It is generally assumed that the primary cause leading to such a loss of intestinal integrity remains often unknown and is believed to be multifactorial. In this study, we hypothesized that one of the factors that compromises the intestinal barrier function is the fungal toxin DON. DON is a secondary metabolite and exotoxin of various fungal species of the genus Fusarium, which are soil-borne and invade living plants prior to harvest. As a small molecule (molecular weight 296.3), it resists technical processes of milling and food processing and can be detected in various food commodities. The high incidence of human exposure is confirmed by the analysis of urine samples for DON and its glucuronides, demonstrating that the exposure incidence exceeds, in many cases, 90% of the tested population (18–21). Experimental data showed that DON inhibits cellular protein synthesis and exerts a ribosomal stress syndrome associated with an inflammatory response, as recently reviewed by Pestka (32) and He et al. (33). Initially, incidental and human exposure to high concentrations of DON was associated with acute gastritis and intestinal distress (15). Recent experimental data with different in vitro systems, however, show that DON already at lower dietary concentrations is able to impair the integrity of epithelial cell monolayers. A dysfunctional epithelial cell barrier may be one of the predisposing factors leading to inflammatory diseases such as food allergy, inflammatory bowel disease, and celiac disease. Here we describe a series of experiments designed to identify the cascade of events exerted by DON that lead to the loss of epithelial barrier integrity in vitro and a compromised intestinal barrier function in vivo in mice exposed orally to DON, resembling human dietary exposure.

Impairment of transepithelial resistance depends on route of exposure

A common early marker of an impairment of epithelial barrier integrity is a decrease in the TEER of an established Caco-2 cell monolayer at DON concentrations that do not affect cell viability. In an initial series of experiments, we demonstrated that concentrations ≤ 12.5 μM DON did not impair Caco-2 cell viability (Fig. 1), a finding that was in agreement with previous results (31). Considering the kinetics of DON, which is rapidly absorbed in the upper intestine (30), but is also secreted into the intestinal lumen, as it is a substrate for ABC efflux transporters (31), we conducted TEER measurements following different routes of exposure. First, increasing concentrations of DON were added to the apical side, mimicking the direct contact of the epithelial cells with contaminated food components. A dose-dependent decrease in TEER of the Caco-2 monolayer was observed after 24 h of DON incubation. This is in agreement with previous studies (12, 13) and the data of De Walle et al. (11), who found a dose-dependent decrease in TEER of Caco-2 cells at concentrations between 0.17 and 17 μM of DON after apical exposure of a cell monolayer. In turn, DON was added to the basolateral compartment to

DEOXYNIVALENOL AND INTESTINAL INTEGRITY BREAKDOWN
Figure 6. DON selectively affected TJ protein levels and localization. Caco-2 cells were grown on inserts and stimulated with increasing concentrations of DON (1.39, 4.17, and 12.5 \( \mu \text{M} \)) in apical and basolateral compartments for 24 h. Caco-2 (continued on next page)
Impairment of epithelial integrity facilitates a paracellular transport of macromolecules in vitro and in vivo

The functional consequences of the readily measured impairment of the cell monolayer integrity was demonstrated by measuring the translocation of the paracellular transport markers LY (0.45 kDa) and FITC-dextran (4 and 40 kDa). On 24 h of exposure, DON induced a significant increase in the translocation of LY and 4-kDa FITC-dextran from the apical compartment to the basolateral side. These findings are in agreement with the data of Pinton et al. (13, 16), who demonstrated that on 48 h of DON exposure, the Caco-2 and IPEC-1 monolayers became more permeable for 4 kDa FITC-dextran (34). In contrast, we found no difference in the permeability of the 40 kDa FITC-dextran, indicating that larger molecules still cannot pass the epithelial barrier. DON-mediated changes in TJs increase paracellular permeability to small molecules, but not transcellular flux of large molecules as this would require disruption of the cellular layer by cell death. The in vivo experiments with B6C3F1 mice, orally exposed to DON confirmed the hyperpermeability as a significant increase in the translocation of FITC-dextran (4 kDa) from the gut lumen to blood circulation was observed in the DON-treated animals. Comparable findings were reported as yet only following exposure of animals to lipopolysaccharide (LPS) and even bacterial pathogens (35, 36).

DON alters function and expression of TJ proteins in vitro and in vivo

The epithelial barrier function relies on TJs eliminating the intercellular space, like ZO proteins that are transmembrane proteins that link the apical membrane proteins (such as OCLN and CLDNs) with cytoskeleton proteins such as actin (37). Disruption of these actin filaments destroys the TJ protein network, thereby decreasing TEER values (38). The first evidence of a direct effect of DON on the TJ network was obtained by the horizontal impedance measurement. The real-time analysis displayed that DON exposure induced an instant drop in impedance already in the first 1–2 h, followed by a marginal recovery, but not a full recovery, within the 24-h test period. These new findings demonstrate pronounced effects already at concentrations as low as 1.39 μM DON, suggesting a direct effect of DON on TJs, sealing the intercellular space. In this study, the measured impedance is based on different frequencies (10, 25, and 50 KHz) merged to one signal;

Figure 7. DON increased in vivo intestinal permeability in B6C3F1 mice. At 2 h after oral DON administration (25 mg DON/kg BW), mice were gavaged with 4-kDa FITC-dextran (500 mg/kg BW). At 4 h after FITC-dextran gavage, the appearance of FITC-dextran was measured in blood, as described in Materials and Methods. Values are expressed as means ± SEM; n = 5–6 animals/group. *P = 0.05 vs. control group.

mimic the secretory pathway of absorbed DON, which is mediated by the efflux transporters ABCB1 (Pg-p) and ABCC2 (MRP2) (31). Interestingly, the decrease in TEER values following basolateral exposure was more pronounced. This finding is in agreement with recent data by Diesing et al. (12), reporting that the basolateral surface of the intestinal barrier seems to be more susceptible to DON, as compared to the apical exposure route, in porcine IPEC-J2 cells. To further substantiate these findings, DON was added to both compartments of the transwell system. The measured decrease of TEER values was almost similar to the effects of a basolateral exposure to DON. Besides this dose-dependent effect of DON on the TEER of Caco-2 monolayers after 24 h, a time-dependent decrease in TEER was observed when comparing different incubation time points (2, 4, 8, and 12 h). Although the gastrointestinal transit time of DON ingested with feed is expected to be <1 d, a 24-h DON incubation time is relevant for the in vivo situation, since DON is a daily food contaminant of wheat and grain products, and intestinal epithelial cells are regularly exposed to DON during a day. Moreover, Azcona-Olivera et al. (28) observed that DON was still measurable in the mouse small (2.50 pmol/mg) and large intestine (7.80 pmol/mg) tissue 24 h after a DON gavage (25 mg/kg). In addition, following absorption in proximal intestine after oral ingestion, DON is likely to be secreted into the colon lumen due to the high expression of efflux transporters along the colon (31).
therefore, we cannot discriminate between transcellular and paracellular impedance contributions. Although, there is a considerable overlap between the real-time impedance and TEER measurements (23), real-time impedance measurements clearly show the time dependency of the events.

Since TEER and impedance measurements suggested alterations of TJ permeability and in order to describe the effect of DON on TJ proteins in more detail, the mRNA expression and protein levels, as well as cellular distribution of different TJ proteins (CLDN1, CLDN3, CLDN4, OCLN, and ZO-1), were measured in Caco-2 cells following DON exposure. PCR analyses pointed out that the mRNA expression of Caco-2 cells exposed to DON for 3 h showed a concentration-dependent up-regulation of the expression levels of CLDN3, CLDN4, and ZO-1, while the mRNA expression levels of all TJ proteins were increased on 6 h of DON exposure.

Figure 8. DON selectively affected TJ mRNA expression levels and their localization in mouse intestine. A–E) Mice received DON by oral gavage (25 mg DON/kg BW). After 6 h, samples from the proximal small intestine (A), middle small intestine (B), distal small intestine (C), caecum (D), and colon (E) were collected, and mRNA levels of TJ proteins (CLDN1, CLDN2, CLDN3, CLDN4, OCLN, and ZO-1) were measured by RT-PCR. Results are expressed as mean ± SEM relative mRNA expression; n = 5–6 animals/group. *p ≤ 0.05, **p < 0.01, ***p < 0.001 vs. control group. F) For immunofluorescence staining, Swiss-rolled paraffin sections obtained from distal small intestines were detected by antibodies for CLDN1, CLDN2, CLDN3, CLDN4, OCLN, and ZO-1, as described in Materials and Methods. n = 4–5 mice/group (2–3 sections/animal). View: X200.
and these results were comparable with the results obtained after 24 h of DON exposure. All individual time points of DON exposure show most probably a compensatory up-regulation of TJ mRNA levels. These results correlate with previous findings with IPEC cells (12) and complete the data of De Walle et al. (11) previously showing a raise in the mRNA expression levels of CLDN4 and OCLN in Caco-2 cells exposed to DON for 24 h. These findings were compared again with the in vivo mouse model by measuring the mRNA expression levels of TJ proteins after a DON gavage. A direct comparison between the in vitro findings in human Caco-2 cells with findings in mice needs to consider possible species differences and the fact that the samples taken in the in vivo study contained the entire intestinal wall, not only the epithelial cell layer; however, a number of interesting similarities in the response to DON were observed. For example, in line with the increase in mRNA expression of TJ proteins in DON-stimulated Caco-2 cells, in DON treated mice, the mRNA expression levels of CLDN2, CLDN3, and CLDN4 were significantly increased in different parts of the intestines (small intestine, caecum, and colon), whereas the ZO-1 mRNA expression levels were only increased in the proximal small intestine of the DON-treated animals. The CLDN1 and OCLN mRNA expression was not significantly affected in the treated mice as compared to the control animals. In the in vivo experiments, CLDN2 was measured in addition to CLDN1, CLDN3, and CLDN4, whereas in Caco-2 cells, CLDN2 is normally not expressed (39). The observed up-regulation of the different CLDNs was most pronounced in the distal part of small intestine. The epithelial cells along the distal part of the small intestine are the most susceptible interface in the intestine, most probably because the distal small intestine is exposed to DON from both luminal and basolateral side (40). DON is quickly and expeditiously absorbed in the upper parts of the small intestine (30, 41) and following absorption, it is likely secreted into the gut lumen, as DON is a substrate for the efflux transporters ABCB1 (P-gp) and ABCC2 (MRP2) (31).

When investigating the protein levels of the TJ proteins CLDN1, CLDN3, CLDN4, OCLN, and ZO-1 in the Caco-2 cells of the in vitro DON model, a dose-dependent reduction of the CLDN1, CLDN3, and CLDN4 protein levels in DON-treated Caco-2 cells compared to untreated cells was demonstrated, while the OCLN and ZO-1 levels remained unchanged after DON stimulation. De Walle et al. (11) and Pinton et al. (13) also showed the absence of a decrease in ZO-1 expression in Caco-2 cells exposed to DON. While these findings reflect the results of the impedance measurements, they also indicate that the TJ network had not entirely

---

**Figure 9.** DON induced histomorphological changes in the intestine of mice. Mice received DON by oral gavage (25 mg DON/kg BW); after 6 h, Swiss rolls obtained from the proximal (A, C, E, G, I) and distal (B, D, F, H, J) small intestine were stained with H&E for histomorphometric analysis of villus height (A, B), villus area (C, D), epithelial cell area (E, F) and related images from control (G, H) and DON-treated mice (I, J). Magnification 200X. Results are expressed as means ± SEM; n = 5–6 animals/group. *P ≤ 0.05, **P < 0.01.
lost its functions. This was also indicated by the observations that very large molecules, such as 40-kDa FITC-dextran, still could not pass the epithelial Caco-2 cell monolayer. These findings are also in agreement with results in other cell lines (11, 12, 16). The decrease in CLDN protein levels is associated with an increase in mRNA expression levels observed after 24 h of DON exposure, which is most likely indicative of a repair mechanism. Whether such repair mechanisms are directly affected by DON at the transcriptional level or are impaired by the previously described nonspecific inhibition of the cellular protein synthesis, as discussed by de Walle et al. (11), remains to be elucidated. The effects of the decrease in protein levels and the compensatory up-regulation of mRNA levels of the measured TJ proteins are visualized by the analysis of the cellular localization of TJ proteins in Caco-2 cells. For the immunofluorescence staining, the Caco-2 cells treated with 4.17 μM DON were used, since concentrations from ~0.5 to 7 μM DON represent plausible intestinal DON concentrations that may be found in the gastrointestinal tract after ingestion of moderately to highly DON-contaminated food, as described by Sergent et al. (14). The samples of immunofluorescence analysis of Caco-2 cell monolayers show the membrane-associated localization of all TJ proteins, while DON-exposed cells exhibit irregular structures of the stained proteins, suggesting clumping and internalization of fragmented networks. These altered distribution patterns were not only observed for the CLDN proteins, which were dose-dependently decreased, but also for OCLN and ZO-1, for which only marginal alteration in the total immunoreactive protein levels could be measured.

It is becoming increasingly apparent that a variety of pathological stimuli, such as proinflammatory cytokines, microorganisms, and toxins, can induce endocytosis of several TJ proteins and as a consequent internalization of TJs. The internalization of TJs can be accompanied by their advanced degradation or a reallocation to the plasma membrane. However, both mechanisms cause increased paracellular permeability due to the significant loss of TJ proteins at the plasma membrane of epithelial cells (42–46).

Comparable to the in vitro and in vivo findings, where the most pronounced effects on TJ proteins were observed in the CLDN family, immunofluorescence analysis of the distal small intestine of mice confirmed that DON exposure mainly affected the CLDN distribution.

The lateral distribution pattern of CLDN1 and CLDN3 over the entire villi in the distal small intestine was observed in control mice, and this typical pattern was even more pronounced after DON exposure, resulting additionally in a visible expression at the basal cytoplasm. As already described by Rahner et al. (47) and Tamagawa et al. (48), CLDN2 is predominantly found in the crypts in mouse small intestine, and this is confirmed in our study, where the CLDN2 was expressed laterally between adjacent cells in the villus crypts. However, after DON gavage this CLDN2 expression pattern is disrupted and not restricted to the crypts anymore, but is distributed along the villi cells. Furthermore, our findings clearly indicate that the expression of CLDN4 is restricted to selective sites, and not found on every tip or crypt of the villus epithelium, which is in agreement with Tamagawa et al. (48). No pronounced effect on the CLDN4 distribution pattern in the distal small intestine was observed after the DON gavage. Unlike the distribution pattern of the CLDNs in the distal small intestine, OCLN and ZO-1 were localized in distinct dot-like structures at the apical region of the lateral plasma membrane in the epithelial cells of the villus, and no clear alterations were observed after DON exposure. Immunofluorescence stainings of different TJ proteins were also performed in the colon of control and DON-treated animals to confirm the PCR analyses suggesting that the distal small intestine is most significantly affected by DON. As expected, no clear differences in the TJ distribution patterns of CLDN1, CLDN2, CLDN3, CLDN4, OCLN, and ZO-1 were observed in the colon of DON-treated animals compared to control animals.

Taken together, it can be concluded that the most pronounced effects of DON on TJ proteins involve the CLDN family, as decreased CLDN levels of the DON-treated Caco-2 cells, as well as increased CLDN levels in mouse intestine and an altered CLDN distribution in the distal small intestine on DON stimulation, were observed. Claudins are known to be determinants of functional barrier properties, including size and charge selectivity of the paracellular permeability of the intestinal epithelium (49, 50). It also can be hypothesized that the CLDNs are more susceptible to DON exposure since these transmembrane proteins contain extracellular domains that may act as a binding site for DON as demonstrated for Clostridium perfringens enterotoxins interacting with CLDN3 (51). Claudins form a selective barrier between adjacent cells in contrast to the intracellular scaffold protein ZO-1, which interacts with intracellular domains of transmembrane proteins anchoring these proteins to the actin cytoskeleton (52).

A subsequently conducted histomorphometric analysis of the intestinal tissue of the DON-exposed mice showed a significant decrease in villus height, villus area and also in the epithelial cell area in comparison to the nontreated animals. This result is in agreement with the data from Pinton et al. (17) reporting a significant reduction in the villus height along jejunum of pigs exposed to a DON-contaminated diet for 4 wk. An ex vivo study by Kolf-Clauw et al. (53) shows alterations of pig jejunal explants, including shortened and coalescent villi, following DON exposure for 4 h. One possible explanation for the shortened villi could be sloughing of epithelial lining from the surface of the villi and apoptosis and necrosis of the epithelial cells, since the epithelial cell area was also decreased in DON-treated animals. However, no prominent histological lesions were observed. Moreover, after acute mucosal injury by DON (at high dosage), villus contraction can take
place, which is the initial phase of repair mechanisms aiming at the restoration of barrier function by reducing the total and denuded surface area of the villi. Villus contractions can be separated in an immediate contraction and second phase ongoing contraction, which progresses in the first hours after injury and is mediated by endogenous prostaglandins (54).

In summary, the comparison of in vitro Caco-2 cell studies with the in vivo murine model suggests that the main molecular target of DON in the intestine is the TJ network. Disintegration of this network is accompanied by a loss of barrier function, which increases the risk of antigen transfer and an inflammatory response. Considering the high prevalence of dietary DON exposure in consumers of grains and grain-based products, the possible contribution of DON to the onset and propagation of inflammatory bowel disease warrant further investigation.
